

NORWAY LOBSTER

Nephrops norvegicus

INTRODUCTION

Fishery of Norway lobster (*Nephrops norvegicus*) started in the early 1950s and during the first two decades it was mainly conducted by Icelandic, Belgian and French vessels (Table 1). The fishery has since 1974 only been conducted by Icelandic vessels. In the beginning Norway lobster was mainly fished during spring and summer and the fleet was large or up to 200 boats in the 1970's. In recent years, the season has been longer, as the fishery starts in the middle of March and ends in November/December. There has been a gradual decrease in number of boats participating in the *Nephrops* fishery and during the last couple of years there have been as few as seven boats active in the fishery. The species is entirely caught in *Nephrops* trawls, but through the decades there have been occasional creel trials.

Fishing grounds in Iceland are at the northernmost part of the species distributional range. For females it has been shown that there is a biennial reproductive cycle and, therefore, slower post-maturity growth than in, for example, Scottish, Irish, French and Portuguese waters of mostly annual spawning (Eiríksson, 2014). That affects the productivity of the stock and warrants lower exploitation rate than applied in other *Nephrops* stocks.

COMMERCIAL FISHING

LANDINGS

Due to poor stock status, a monitoring fishery was conducted for the second year in 2020 and the fishing grounds Jökuldjúp southwest of Iceland and Lónsdýpi southeast of Iceland were again closed for *Nephrops* fishing. As such, 194 tonnes of *Nephrops* were landed in 2020, which is a reduction of 63 tonnes from the previous year (Table 1, Figure 1). The catch has steadily declined since 2010 when it was 2540 tonnes. There have been periodic fluctuations in landings since the onset of the fishery in the 1950's, which soon reached 6000 tonnes in 1963, following a few years with high catches (Eiríksson and Jónasson, 2018).

In 2020, 84 tonnes were landed from the southwestern grounds, a reduction of 75 tonnes from the previous year (Table 2, Figure 2). On the southern grounds only 1 ton was landed. In the southeast area, 109 tonnes were landed, an increase of 15 tonnes from previous year.

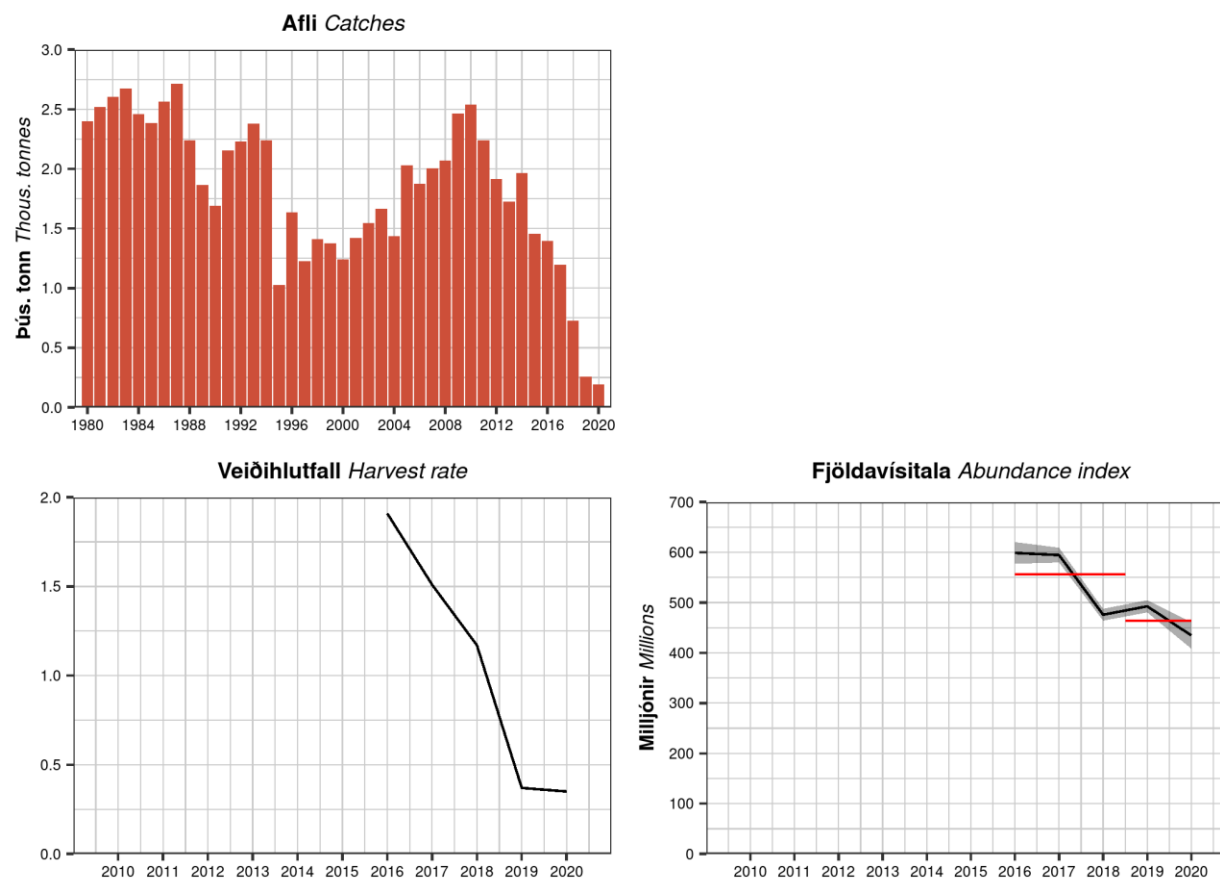

Figure 1. Norway lobster. Catches, harvest rate (sum of landings in numbers, divided by total abundance), stock abundance (Underwater TV, millions; SSB proxy, 95% confidence intervals). Red horizontal lines indicate average abundance indices for 2016–2018 and for 2019–2020 used in the advice calculations

CPUE AND EFFORT

Catch per unit effort (CPUE, standardized to 1 trawl and the period May–August) declined between 2019 and 2020 or from 23.4 to 14.8 kg per hour towed (Table 2). CPUE has declined drastically since the peak in 2007 and 2008 when more than 100 kg of *Nephrops* were caught per hour towed. There have been overall similar fluctuations between areas with regards to CPUE (Figure 3). CPUE has on average been higher in the southeast area, and in recent years it has been lowest in the southern area.

There was a decreasing trend in the fishing effort from 1970 to 2000–2008, depending on areas. Since 2008, there has been a decrease in effort in the southern area, an increase in southwestern area, but effort has not changed much in the southeastern area (Figure 4). In the monitoring fishery of 2020, the effort increased between years in the southeastern areas.

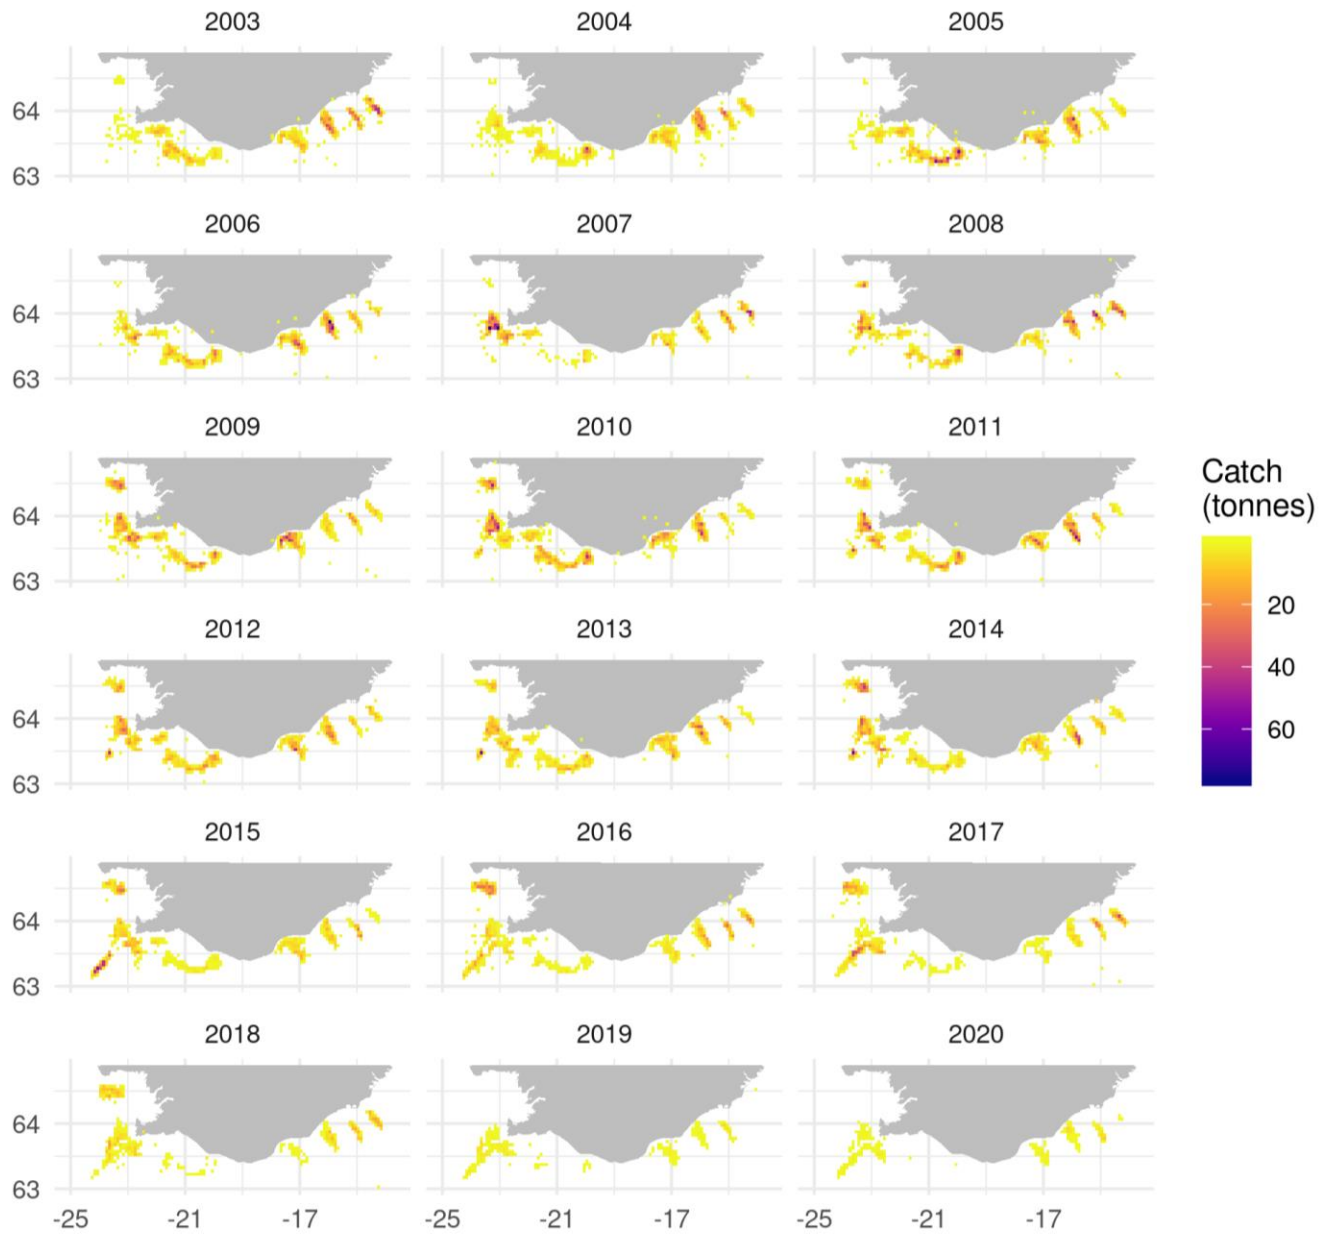

Figure 2. Norway lobster. Distribution of catches in 2003-2020.

Figure 3. Norway lobster. Standardized CPUE in 1970–2020 in the SW- (black), Vestmannaeyjar- (south) (red) and SE areas (green).

Figure 4. Norway lobster. Standardized effort in 1970–2020 in the SW- (black), Vestmannaeyjar- (south) (red) and SE-areas (green).

LENGTH DISTRIBUTIONS

In 2020, 55 length samples were obtained from the landed catch and the survey. The most frequent sizes (CL) of males in the samples in 2018 were around 62 mm (Figure 5). In recent years very few small *Nephrops* have been caught and in 2020 there was a low ratio of *Nephrops* smaller than 40 mm CL recorded. Large proportion was above 60 mm and the ratio of animals over 70 mm CL was large.

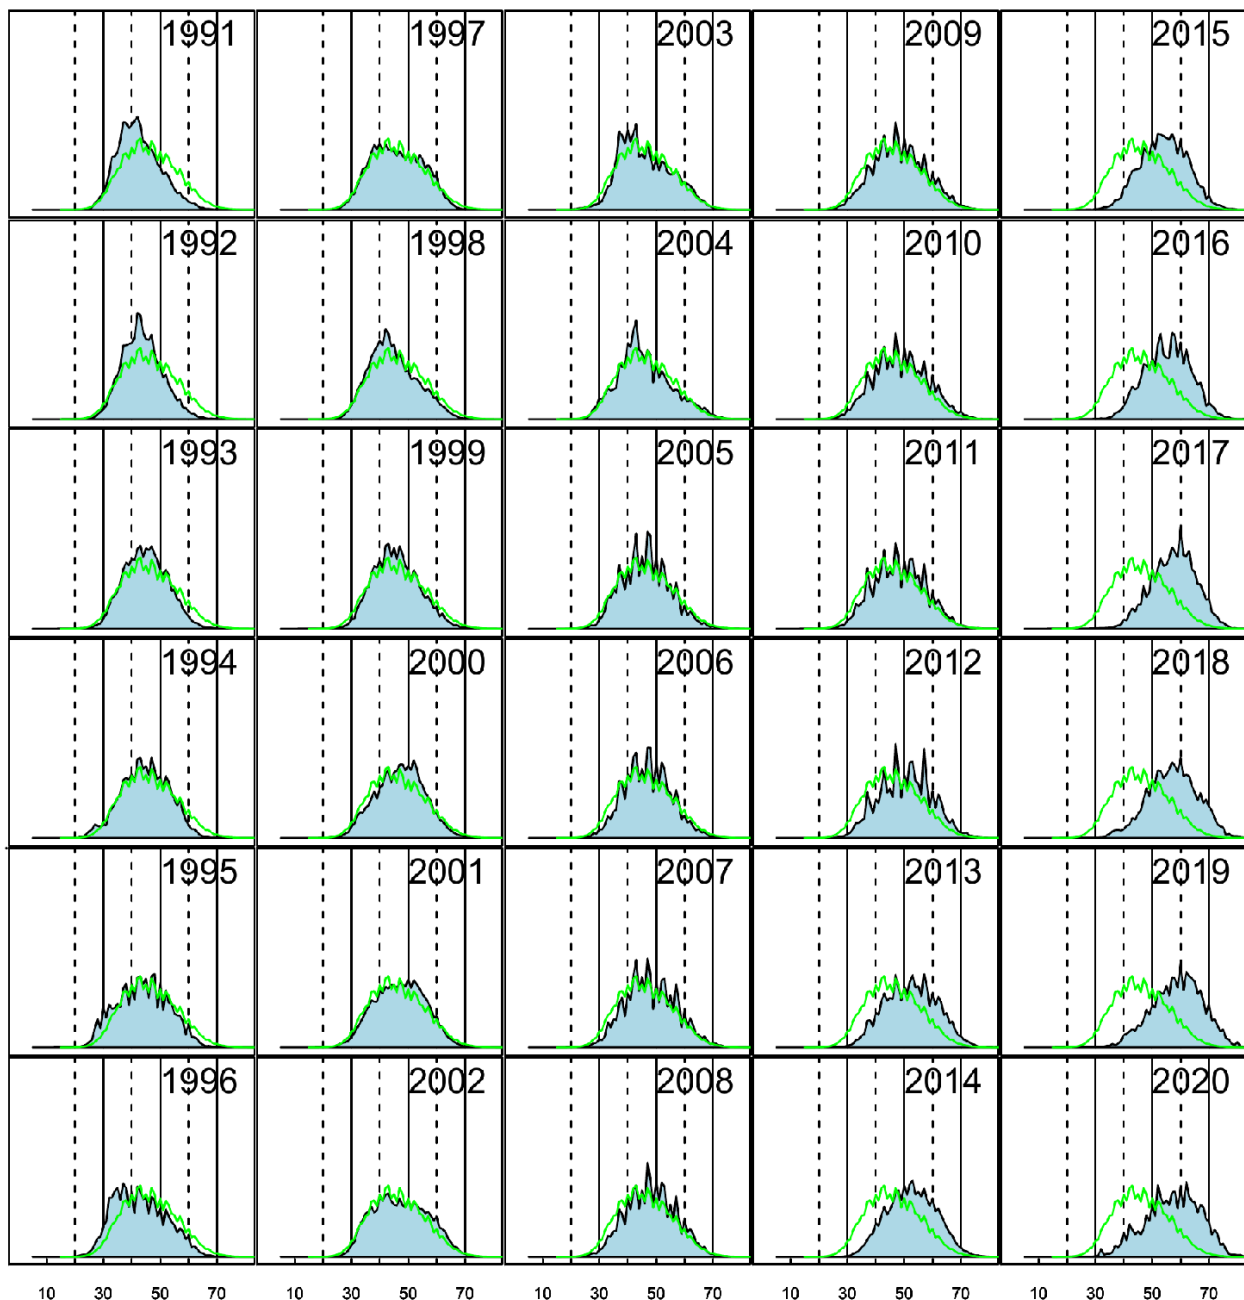

Figure 5. Norway lobster. Length frequency distribution (shaded area) of all samples 1991–2020. The green line shows the average of the years 1970–2020.

SURVEYS

Figure 6. Norway lobster. Polygons of *Nephrops* grounds (see Figure 2) based on VMS data. See name of grounds marked by the red number in Table 4.

UWTV SURVEY

The first UWTV survey in Icelandic water was conducted in June 2016, following a pilot study in Jökuldjúp in April. In total, 86 UWTV-stations on a roughly 4.5 nautical mile grid were completed on all known *Nephrops* grounds in 2016. The size of the *Nephrops* area was estimated from VMS data. A minimum of 6 pings from *Nephrops* vessel at fishing speed on 800*800 meters resolution grid was used as a threshold, which approximately includes 99% of the pings. Adjoining grids are then combined and fishing grounds smaller than 4 km² are excluded. The total size of the fishing grounds was estimated to be 5989 km² based on data from 2007–2016, but there was a gradual shift to fishing on new or connected grounds in 2017 and 2018, especially in the SW area. The estimated size of *Nephrops* grounds in 2018 was 6588 km² (Table 4, Figure 6). In total there were nine distinct areas ranging from 247 km² to 1400 km². The largest ground (Vestmannaeyjar) is in the southern part (Háfadjúp to Selvogsbanki) and the smallest one is Lónsdjúp in the east. Three grounds were split up into 2–3 patches: Vestmannaeyjar, Hornafjarðardjúp and Selvogsgrunn.

The total number of *Nephrops* in the survey conducted in June 2020 on all Icelandic grounds was estimated to be 434 million animals, a decrease from 492 million animals in 2019. Average density in 2020 was 0.065 burrows per square meter (Table 4, Figure 7). Highest density of burrows was in Breiðamerkurdjúp; 0.09 burrows per m² (Figure 8 and 9). The largest ground (Vestmannaeyjar, 1400 km²) had the lowest density or 0.06 burrows per m². Visibility was poor in deeper part of Hornafjarðardjúp and Lónsdjúp during the UWTV survey and the deepest station in Lónsdjúp was left out. Results from 2016–2019 are shown in Figures 10 and 11.

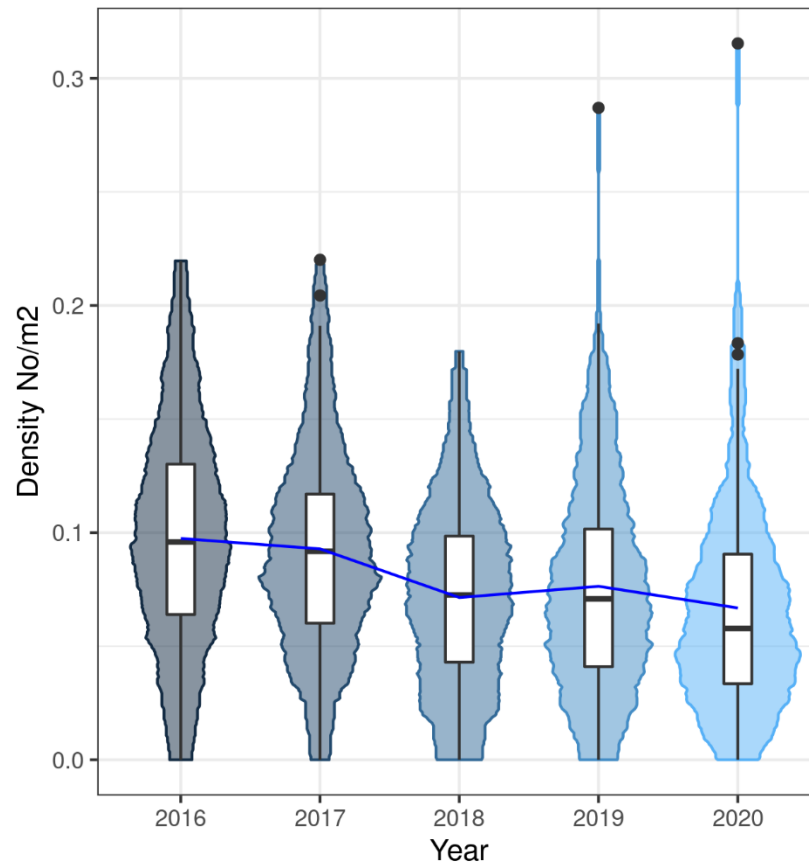

Figure 7. Norway lobster. Violin and boxplots of adjusted burrow density distributions by year 2016-2020. The blue line indicates the mean density over time. The horizontal black lines represent the median, white boxes are the inter quartile ranges, the black vertical lines show the range, and the black dots are outliers.

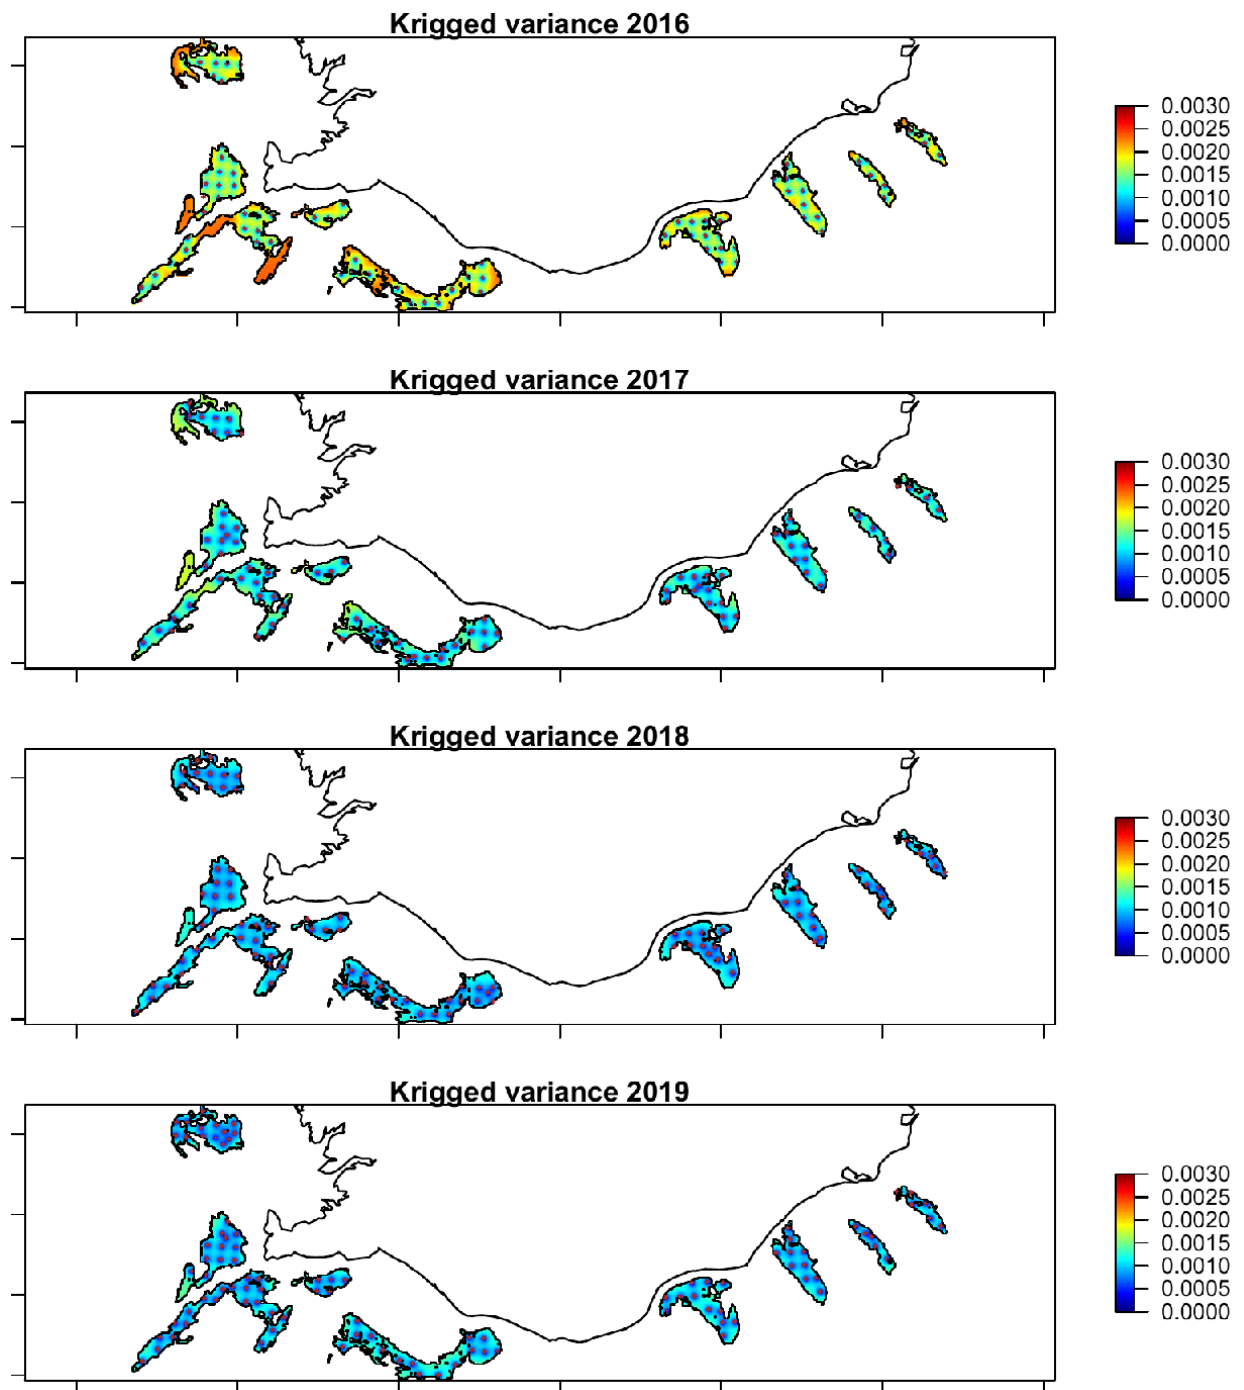

Figure 11. Norway lobster. Krigged variance of burrows density on *Nephrops* ground from the UWTV surveys conducted in 2016-2019. The brown crosses represent the stations.

LARVAE SURVEY

During the 2018 UWTV survey, 23 bongo-net stations (500 μm mesh size) were accomplished for the first time after the completion at every fourth UWTV station. The objective is to estimate recruitment of *Nephrops*. The bongo-net was towed in a V-shaped manner down to 40 m and up to the surface. In 2019 and 2020, 28 and 25 stations were conducted, respectively. *Nephrops* larvae were found on 10 stations in 2018, on 19 in 2019 and 15 in 2020 (Figure 12). The average density was 15.1 larvae per 1000 m^3 in 2018, 24.8 larvae per 1000 m^3 in 2019 and 8.1 larvae per 1000 m^3 during the 2020 survey. The distribution was wider in the 2019 and 2020 surveys. During all years, all the Zoea stages (I–III) were found in the southeast region. The information from this sampling can be indicative of future recruitment.

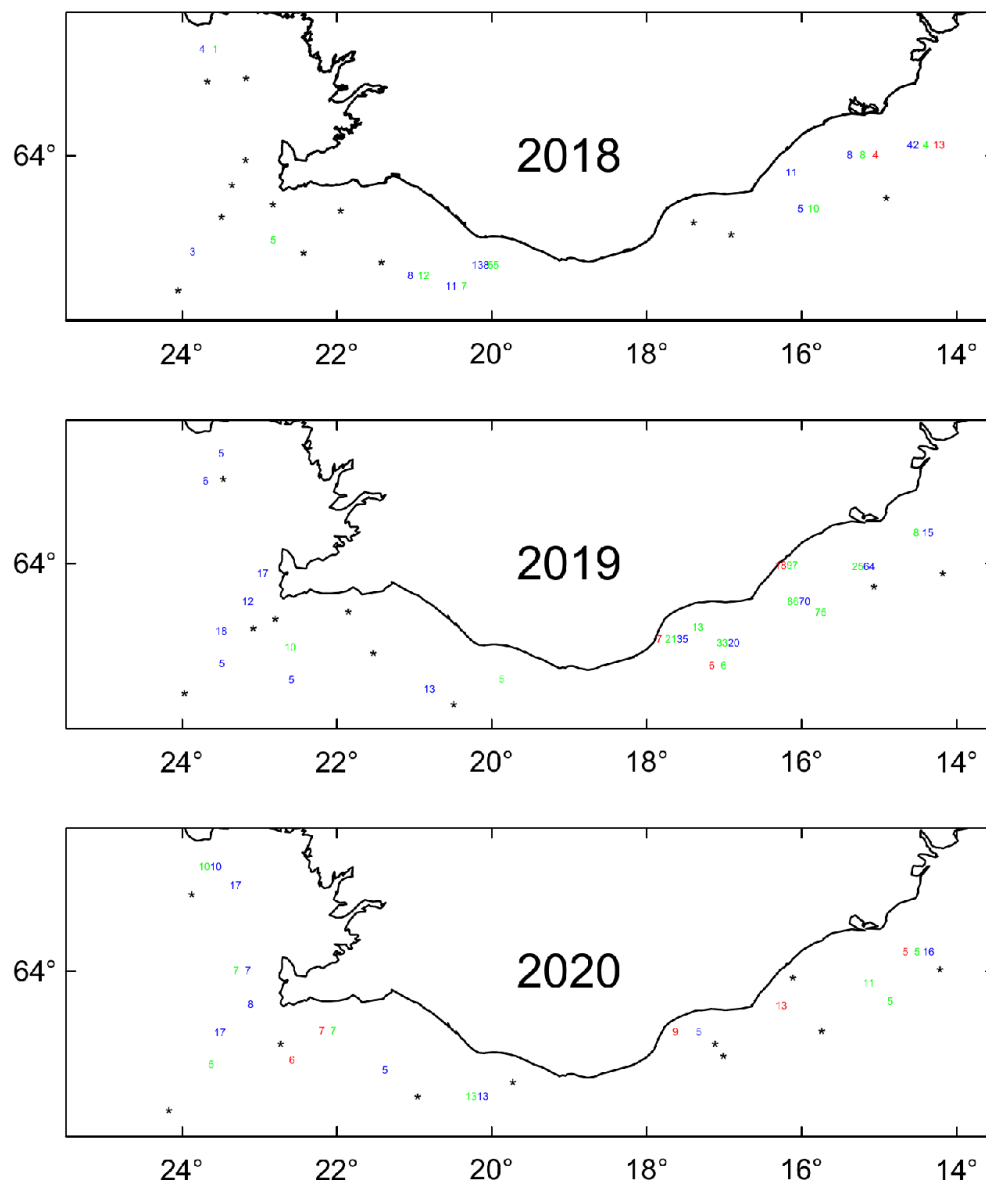

Figure 12. Norway lobster. Number of *Nephrops* larvae caught in bongo-net per 1000 m^3 from surveys conducted in 2018 to 2020. Blue numbers indicate larvae on Zoea stage 1, green Zoea stage 2, and red Zoea stage 3. Black asterisks are stations where no *Nephrops* larvae were found.

TRAWL SURVEY

A *Nephrops* trawl survey was conducted from 1973 to 2015. In the survey, 55 standardized two-hour tows were conducted on all *Nephrops* grounds. The stock abundance index declined from the peak in 2009 and reached the lowest value in 2015. There have been some similarities between the stock index and CPUE, but less in recent years and during the early years of the survey. Catchability has been related to water clarity (mainly due to phytoplankton) with generally higher catches in murkier waters, and with less *Nephrops* when groundfish numbers are high. This is reflected in the biology and the burrowing behavior of *Nephrops* as the strong temporal patterns in catch rates make the traditional trawl surveys unfeasible to estimate abundance. This led to the progress of using UWTV survey in 2016 to assess stock development and provide management advice for the *Nephrops* stock in Icelandic waters (Campbell, *et al.*, 2009).

BOTTOM TRAWLING ON *NEPHROPS* GROUNDS

TRAWLING INTENSITY

In addition to trawling with *Nephrops* trawl, a considerable amount of bottom trawling for groundfish occurs on *Nephrops* grounds. There are around 6600 towed hours annually (2014-2018) on *Nephrops* grounds (Table 5). Most of the activity is on the Vestmannaeyjar *Nephrops* ground or almost 4000 towed hours (2.4 hours annually per km²). Slightly higher trawling activity is in Breiðamerkjardjúp or 2.5 h per km² and high trawling activity is also in Hornafjarðardjúp (0.9 h per km²) and Lónsdjúp (0.7 h per km²). On average, the CPUE of cod (*Gadus morhua*), the most important demersal fish species, south of 65°N is 0.5 tonnes per hour towed (Table 8). The CPUE of cod was high within Vestmannaeyjar grounds (1.2 t/h), but lower than average in the eastern *Nephrops* areas, i.e., Breiðamerkjardjúp, Hornafjarðardjúp and Lónsdjúp, or around 0.3 t/h in all regions (Figure 13, Table 5). CPUE of haddock (*Melanogrammus aeglefinus*) and ling (*Molva molva*) is also higher within the Vestmannaeyjar region compared to other areas south of 65°N (Table 5).

Because of poor state of the *Nephrops* stock, it is proposed to close the core *Nephrops* areas southeast of Iceland from additional disturbance of groundfish bottom trawling to protect the observed recruitment (Figure 13, Table 5). Those areas have relatively high trawling activity but are of less importance for groundfish than the Vestmannaeyjar grounds.

Recommended boundaries of closures for bottom trawling on Nephrops grounds:

Breiðamerkurdjúp

1. 63°52'50''N - 16°16'00''V
2. 63°35'00''N - 15°46'00''V
3. 63°37'00''N - 15°41'00''V
4. 63°57'50''N - 16°02'00''V
5. 63°52'50''N - 16°16'00''V

Hornafjarðardjúp

1. 64°00'00''N - 15°18'00''V
2. 63°43'00''N - 14°52'00''V
3. 63°46'00''N - 14°47'00''V
4. 64°00'00''N - 15°10'00''V
5. 64°00'00''N - 15°18'00''V

Lónsdjúp

1. 64°10'00''N - 14°42'00''V
2. 63°56'00''N - 14°12'00''V
3. 63°56'00''N - 14°05'00''V
4. 64°10'00''N - 14°30'00''V
5. 64°10'00''N - 14°42'00''V

Figure 13. Norway lobster. Polygons of *Nephrops* grounds based on VMS data in southeastern Iceland. Proposed closed areas for bottom trawling within *Nephrops* areas are plotted (red lines) and depth contours (100 and 200 m, grey lines).

HARVEST RATE

According to the UWTV survey, the harvest rate in 2020 varied from 0–2.3% between grounds, with an average harvest rate of 0.35% (Table 4). Limited fisheries were on Vestmannaeyjar and Selvogsbanki with subsequently low harvest rate. The highest harvest rate was in Hornafjarðardjúp, followed by Breiðamerkurdjúp. The ratio of males in the catches was 50–99%. Unusually high amounts of females were caught in Hornafjarðardjúp in 2020 (Table 4), similar condition as seen in Breiðamerkurdjúp in 2019, as the ratio of males in the catches is usually around 90%.

With declining catches, the harvest rate has declined from 1.91% in 2016 to 0.35% in 2020 (Figure 1). During the monitoring fishery of 2020, the harvest rate increased in Hornafjarðardjúp between years, but with less fluctuations on other areas (Figure 14). Despite the disjointed nature of the *Nephrops* ground in Iceland and therefore relatively small number of stations on each ground, the relative abundance shows similar fluctuations on separated grounds (Figure 8, 10 & 14). The trends are similar on the closed grounds Jökuldjúp and Lónsdjúp as within the open areas. Many of the grounds have also experienced low harvest rate.

Figure 14. Norway lobster. Relative burrow abundance (solid line) and harvest rate (dotted line) in individual subareas (Eyjar–area 1, Hornafjardar – area 2, Jokul – area 3, Lons – area 4, Eldey – area 5, Breida area 6, Grinda – area 7, Selvogur – area 8 and Skeidar – area 9) during 2016 – 2020 (See Figure 6 for area id locations).

Table 4. Norway lobster. Summary of 2020 UWTV survey and information about the catch in 2020. Name of an area, id of area (see Figure 6), size of the area (km²), number of burrows (million), mean number of burrows per meter square, catches per area, mean weight of *Nephrops* in catch, ratio of males in the catch (%), number of animals removed (million) and harvest rate.

Area	Id	km ²	Burrows	Burrows m ²	Catch (t)	M.weight (g)	M%	Removals	Harvest rate

Table 5. Summary of the average (2014-2018) annual bottom trawl effort on *Nephrops* grounds and all areas south of 65°N. Effort is in hours, E / km² is the effort per km² on *Nephrops* ground. Cod, haddock and ling is the average tonnes caught per species with bottom trawl and CPUE is the tonnes caught per hour for given species.

Area	id	Effort	E / km ²	Cod	C CPUE	Haddock	H CPUE	Ling	L CPUE
